(Dated: December 17, 2008)

We address, on the example of a simple solvable model, the issue of whether the stationary state of dissipative systems converges to an equilibrium state in the low dissipation limit. We study a driven dissipative Zero Range Process on a tree, in which particles are interpreted as finite amounts of energy exchanged between degrees of freedom. The tree structure mimicks the hierarchy of length scales; energy is injected at the top of the tree ('large scales'), transferred through the tree and dissipated mostly in the deepest branches of the tree ('small scales'). Varying a parameter characterizing the transfer dynamics, a transition is observed, in the low dissipation limit, between a quasi-equilibrated regime and a far-from-equilibrium one, where the dissipated flux does not vanish.

PACS numbers: 05.40.-a, 02.50.Ey, 47.27.eb

One of the main challenges of non-equilibrium statistical physics is to understand which principles rule the description of nonequilibrium stationary states. Generic approaches, like linear response theory [1], have been developed for weakly driven systems (for instance gently stirred fluids, or systems subjected to small temperature gradients). In this situation, when the external forcing is very small, the system remains close to an equilibrium state, and the effect of the small drive is thus perturbative. A different situation, which also attracted a lot of interest, is that of dissipative systems, in which an energy flux takes place between scales rather than in real space. Energy is usually injected at large scales, and cascades down, through non-linear interactions, to smaller scales where it is dissipated. Examples include hydrodynamic turbulence [2, 3], wave turbulence in fluids or plasma [4], ferrofluids [5] and vibrating plates [6, 7], fracture [8] and friction [9], as well as granular materials [10, 11] and foams [12]. Dissipative effects are usually characterized by a dissipation parameter, like viscosity or inelasticity coefficients, which is zero in the conservative case. A natural question is to know whether in the limit of small, but nonzero dissipation coefficients, the stationary state of the system becomes close to some equilibrium state to be determined. Qualitatively, one may expect that adding a tiny amount of injection and dissipation to a conservative system breaks energy conservation, but leads to small fluctuations around a given energy level selected by the injection and dissipation mechanisms. The system would thus merely behave as if it was at equilibrium at this energy, and a perturbative approach around an equilibrium state may be meaningful.

Whether this scenario holds in general is certainly an open issue. Perturbative approaches around equilibrium states for dissipative systems have been proposed in the context of two-dimensional turbulence [13, 14, 15, 16, 17, 18], for which the flux of dissipated energy vanishes in the small viscosity limit [3]. However, in other situations like

three-dimensional turbulence [3] or granular gases [19], the dissipated flux seems to remain finite for small viscosity, suggesting that the statistical state of the system does not converge to any equilibrium state.

In order to give further insights into these issues, simple solvable models may be helpful. Here, we study a stochastic transport model, namely a Zero Range Process [20, 21], that describes in a schematic way the transfer of energy between scales, in the presence of injection and dissipation. To account for the specific organization of scale space, where small scales are much more “numerous” than large scales, we define our model on a tree geometry. We show that depending on the energy transfer dynamics, the dissipative stationary state of the model converges in the weak dissipation limit either to an equilibrium state, or to a well-defined far-from-equilibrium state with a finite dissipated flux.

The model is defined on a tree composed of M successive levels (see Fig. 1); at any given level $j < M$, all sites have $m > 1$ forward branches that link them to level $j + 1$, so that the number of sites at level j is m^{j-1} . Sites are thus labeled by the level index j , and the index $i = 1, \dots, m^{j-1}$ within level j . The energy on each site (j, i) of the tree is assumed to take only discrete values proportional to an elementary amount ε_0 , namely

FIG. 1: Sketch of the model, illustrating the tree geometry.

$\varepsilon_{j,i} = n_{j,i}\varepsilon_0$. Energy transfer proceeds as follows: an energy amount ε_0 is moved, either forward or backward, along any branch between levels j and $j+1$ with a rate ν_j . In the absence of driving and dissipation, the dynamics satisfies detailed balance. Energy injection is implemented by connecting the site $(1,1)$ to a thermostat of

temperature $T_{\text{ext}} = \beta_{\text{ext}}^{-1}$, with a coupling frequency ν_{ext} . Dissipation proceeds through the random withdrawal of an amount of energy ε_0 at site (j,i) with rate Δ_j . The master equation governing the evolution of the probability distribution $P(\{n_{j,i}\}, t)$ reads:

$$\begin{aligned} \frac{\partial P}{\partial t}(\{n_{j,i}\}, t) = & - \left(\sum_{j=1}^{M-1} m^{j-1} (2m\nu_j + \Delta_j) + m^{M-1} \Delta_M + \nu_{\text{ext}} (1 + e^{-\beta_{\text{ext}}\varepsilon_0}) \right) P(\{n_{j,i}\}, t) \\ & + \sum_{j=1}^{M-1} \sum_{i=1}^{m^{j-1}} \sum_{l=1}^m \nu_j [P(n_{j,i} + 1, n_{j+1,(i-1)m+l} - 1, \{n_{q,r}\}, t) + P(n_{j,i} - 1, n_{j+1,(i-1)m+l} + 1, \{n_{q,r}\}, t)] \\ & + \sum_{j=1}^M \sum_{i=1}^{m^{j-1}} \Delta_j P(n_{j,i} + 1, \{n_{q,r}\}, t) + \nu_{\text{ext}} [P(n_{1,1} + 1, \{n_{q,r}\}, t) + e^{-\beta_{\text{ext}}\varepsilon_0} P(n_{1,1} - 1, \{n_{q,r}\}, t)]. \quad (1) \end{aligned}$$

In this last equation, $\{n_{q,r}\}$ is a short-hand notation for all the variables that are not explicitly listed. Turning to the stationary state, we look for a steady-state probability distribution of the form:

$$P_{\text{st}}(\{n_{j,i}\}) = \frac{1}{Z} \prod_{j=1}^M \prod_{i=1}^{m^{j-1}} e^{-\beta_j n_{j,i}\varepsilon_0} \quad (2)$$

where β_j is an 'effective' inverse temperature (to be determined) associated to level j , and Z is a normalization factor. Inserting expression (2) of the stationary distribution into the master equation (1) yields a set of equations to be satisfied by the parameters $z_j = \exp(-\beta_j\varepsilon_0)$, for $j = 2, \dots, M-1$:

$$\nu_{j-1}(z_{j-1} - z_j) - m\nu_j(z_j - z_{j+1}) = \Delta_j z_j \quad (3)$$

with the boundary conditions

$$\nu_{\text{ext}}(e^{-\beta_{\text{ext}}\varepsilon_0} - z_1) - m\nu_1(z_1 - z_2) = \Delta_1 z_1 \quad (4)$$

$$\nu_{M-1}(z_{M-1} - z_M) = \Delta_M z_M. \quad (5)$$

Note that these equations correspond to the local balance of the diffusive fluxes $\nu_j(z_j - z_{j+1})$ and dissipative fluxes $\Delta_j z_j$. In the absence of dissipation, namely if $\Delta_j = 0$ for all j , the equilibrium solution $\beta_1 = \dots = \beta_M = \beta_{\text{ext}}$ is recovered. To study the dissipative case, we need to choose a specific form of the frequency ν_j and the dissipation rate Δ_j . A generic form is the following:

$$\nu_j = \nu_0 k_j^\alpha, \quad \Delta_j = D k_j^\gamma, \quad \gamma > 0, \quad (6)$$

where we have introduced a pseudo-wavenumber $k_j = m^{j-1}$, to map the tree structure onto physical space. Parameters ν_0 and D are respectively a frequency characterizing the large scale dynamics, and a dissipation coefficient. We impose the condition $\alpha < \gamma$, so that dissipation becomes the dominant effect at small scales (large

k_j). The transfer rate ν_j and the dissipation rate Δ_j are balanced for a wavenumber $k_j = K$ given by

$$K = \left(\frac{\nu_0}{D} \right)^{1/(\gamma-\alpha)}, \quad (7)$$

which goes to infinity in the limit of small dissipation coefficient D . Note that ν_0/D is similar to the Reynolds number in hydrodynamics. For large K , we shall call the ranges $k_j \ll K$ and $k_j \gg K$ the "inertial" and "dissipative" ranges respectively.

The solution of Eqs. (3), (4) and (5) can be evaluated numerically. We are interested in the inertial range behavior, where energy transfer dominates over dissipative effects, so that we shall explore the solutions by varying α while keeping γ fixed. We first compute the mean energy flux Φ injected by the reservoir,

$$\Phi = \nu_{\text{ext}} (e^{-\beta_{\text{ext}}\varepsilon_0} - e^{-\beta_1\varepsilon_0}). \quad (8)$$

The flux Φ is plotted as a function of α in Fig. 2(a), for a broad range of values of the dissipation coefficient D . We observe a transition around the value $\alpha = -1$: for $\alpha < -1$, $\Phi \rightarrow 0$ when $D \rightarrow 0$, while for $\alpha > -1$, Φ converges to a finite value in the small D limit. These two regimes are also clearly seen in Fig. 2 (b), (c), and (d) by plotting the temperature $T_j = \beta_j^{-1} = -\varepsilon_0 / \ln z_j$ as a function of $\ln k_j = (j-1) \ln m$. A first trivial observation is that K increases more rapidly when decreasing D for larger values of α . More interestingly, we observe that for $\alpha = -2$ [Fig. 2(b)], the temperature profile slowly converges to the equilibrium profile $T_j^{\text{eq}} = \beta_{\text{ext}}^{-1}$ when $D \rightarrow 0$, while for $\alpha = 1$ [Fig. 2(c) and (d)], it converges to a well-defined nonequilibrium profile, which is linear for $k_j \lesssim K$ when plotting β_j as a function of $\ln k_j$ [see Fig. 2(c)]. These results can be interpreted as follows.

FIG. 2: Numerical solution of Eqs. (3), (4) and (5) for $\gamma = 2$ and $D = 10^{-x}$, with x given in (a); same symbols for all four figures. (a) Energy flux Φ as a function of α ; the full line is Φ_0 given in Eq. (10). (b) Temperature $T_j = \beta_j^{-1}$ versus $\ln k_j$ for $\alpha = -2$; the full line is T_{ext} . (c) β_j versus $\ln k_j$ for $\alpha = 1$; full line: β_j^{neq} defined in Eq. (14). (d) Same data as (c) plotted as T_j , on the same window of $\ln k_j$ as (b). Arrows in (b) and (c) indicate the value of K for each D . Other parameters: $M = 50$, $m = 2$, $\nu_0 = 1$, $\nu_{\text{ext}} = 0.1$, $\beta_{\text{ext}} = 1$, $\varepsilon_0 = 1$.

When the transfer mechanism is inefficient at small scales ($\alpha < -1$), dissipative scales are not “fed”, so that energy accumulates at large scales, generating an effective equilibrium. In the opposite case ($\alpha > -1$), the transfer mechanism is efficient at small scales, thus “pumping” energy from large scales to dissipative ones.

Most of the above behavior can be understood using a simpler form of the dissipation, which leads to analytically tractable calculations. We assume that $\Delta_j = 0$ for all $j < M$, leaving a nonzero dissipation rate Δ_M only on the last level $j = M$ of the tree. As a first step, we look for the solutions of Eqs. (3) and (4) with $\Delta_j = 0$, $j = 1, \dots, M-1$, without taking into account the dissipative boundary condition (5). We find a family of solutions, parameterized by the flux Φ :

$$z_j = e^{-\beta_{\text{ext}}\varepsilon_0} \left[1 - \Phi \left(\frac{1}{\Phi_0} - \frac{1}{B k_j^{1+\alpha}} \right) \right], \quad (9)$$

where $j = 1, \dots, M$, and with Φ_0 and B given by

$$\Phi_0 = \frac{\nu_0(m - m^{-\alpha})\nu_{\text{ext}} e^{-\beta_{\text{ext}}\varepsilon_0}}{\nu_0(m - m^{-\alpha}) + \nu_{\text{ext}}}, \quad (10)$$

$$B = \nu_0(m - m^{-\alpha}) e^{-\beta_{\text{ext}}\varepsilon_0}. \quad (11)$$

Note that z_j smoothly converges to $e^{-\beta_{\text{ext}}\varepsilon_0}$ when $\Phi \rightarrow 0$, and is a decreasing function of k_j for $\Phi > 0$. Interestingly,

Eq. (9) imposes an upper bound Φ_{max} on the flux Φ , which is determined by the condition $z_M > 0$:

$$\Phi_{\text{max}} = \left(\frac{1}{\Phi_0} - \frac{1}{B k_M^{1+\alpha}} \right)^{-1}. \quad (12)$$

If $\alpha < -1$, one finds for large M that $\Phi_{\text{max}} \approx |B| k_M^{-|1+\alpha|}$, so that $\Phi_{\text{max}} \rightarrow 0$ when $M \rightarrow \infty$. Accordingly, whatever the small scale boundary condition, the flux vanishes in the large size limit. In contrast, if $\alpha > -1$, Φ_{max} converges to $\Phi_0 > 0$ in the large size limit $M \rightarrow \infty$; Φ_0 goes to zero linearly with α when $\alpha \rightarrow -1^+$.

We now use the dissipative boundary condition (5) to determine the precise value of the flux. Eq. (5) states that the diffusive flux Φ is equal to the dissipated flux on level $j = M$. This condition leads to $\Phi = m^{M-1} \Delta_M z_M$, or using $k_M = m^{M-1}$, $z_M = \Phi / (k_M \Delta_M)$. Equating this value of z_M with that given in Eq. (9) for $j = M$, yields an equation for Φ , which is solved into

$$\Phi = \Phi_{\text{max}} \left(1 + \frac{e^{\beta_{\text{ext}}\varepsilon_0} \Phi_{\text{max}}}{k_M \Delta_M} \right)^{-1}. \quad (13)$$

Identifying k_M with the value K defined in Eq. (7), we get $\Delta_M = DK^\gamma = \nu_0 K^\alpha$, and thus $k_M \Delta_M = \nu_0 K^{1+\alpha}$. For $\alpha < -1$, both $k_M \Delta_M$ and Φ_{max} are for large K proportional to $K^{-|1+\alpha|}$, so that their ratio is a constant. From Eq. (13), Φ goes to zero as a finite fraction of the maximum flux Φ_{max} . Using $K \sim D^{-1/(\gamma-\alpha)}$, the flux Φ behaves in terms of the dissipation coefficient as $\Phi \sim D^\mu$ when $D \rightarrow 0$, with $\mu = |1+\alpha|/(\gamma-\alpha)$. From Eq. (9), $\beta_j \rightarrow \beta_{\text{ext}}$ when $D \rightarrow 0$, as long as $k_j \ll K$. Altogether, the effect of dissipation on the system may be considered as perturbative in the case $\alpha < -1$. The perturbation expansion is however singular, with a nontrivial exponent $\mu < 1$. In the opposite case $\alpha > -1$, $\Phi_{\text{max}} \rightarrow \Phi_0 > 0$, while $k_M \Delta_M \rightarrow \infty$. Hence from Eq. (13), Φ is equal for large K (or small D) to the maximum flux $\Phi_{\text{max}} = \Phi_0$, consistently with Fig. 2(a) [23]. From Eq. (9), the temperature profile $\beta_j = -\varepsilon_0^{-1} \ln z_j$ converges to a well-defined nonequilibrium profile

$$\beta_j^{\text{neq}} = \frac{1}{\varepsilon_0} (1 + \alpha) \ln k_j + \beta_{\text{ext}} + \frac{1}{\varepsilon_0} \ln C, \quad (14)$$

with $C = 1 + \nu_0(m - m^{-\alpha})/\nu_{\text{ext}}$. Although this profile has been obtained with a simplified version of the model, one sees on Fig. 2(c) that β_j computed numerically in the original model also converges to β_j^{neq} . Let us emphasize that β_j^{neq} does not depend on parameters related to dissipation [24], but only on parameters characterizing injection and transfer. The temperature profile is continuous with α , namely $\beta_j \rightarrow \beta_{\text{ext}}$ when $\alpha \rightarrow -1^+$. Note also that the coupling ν_{ext} simply “renormalizes” the inverse temperature β_{ext} ; the low coupling limit corresponds to driving the system with a small effective temperature.

To sum up, it turns out that an equilibrium approach to the stationary state of the present model in the weak

FIG. 3: (a) $\langle Y \rangle$ as a function of α , for $D = 10^{-x}$; Y is defined in Eq. (15), with here $f(n) = n$ and $g(k) = k^{-2}$. The full line is the asymptotic value of $\langle Y \rangle$ for $D \rightarrow 0$. (b) Normalized entropy S/N_K versus α , for the same values of D as (a). Other parameters: same as in Fig. 2.

dissipation limit is meaningful if $\alpha < -1$. In this case, the probability distribution $P_{st}(\{n_{j,i}\})$ converges, in a weak sense, to the equilibrium distribution of temperature β_{ext} . Although some deviations from equilibrium persist at small scale in the distribution for $D \rightarrow 0$, the average value of “large scale” observables converges to the corresponding equilibrium value. Such “large scale” quantities, which are not sensitive to small scale details of the distribution, include observables Y defined as

$$Y = \sum_{j=1}^M \left(g(k_j) \sum_{i=1}^{m^j-1} f(n_{j,i}) \right), \quad (15)$$

where $f(n)$ is an arbitrary function, and $g(k)$ satisfies $kg(k) \rightarrow 0$ when $k \rightarrow \infty$. In the opposite case $\alpha > -1$, the probability distribution $P_{st}(\{n_{j,i}\})$ converges when $D \rightarrow 0$ to a well-defined nonequilibrium probability distribution $P_{neq}(\{n_{j,i}\})$, given by Eqs. (2) and (14) [25]. The convergence of $\langle Y \rangle$ to $\langle Y \rangle_{eq}$ for $\alpha < -1$ and to $\langle Y \rangle_{neq}$ for $\alpha > -1$ is illustrated on an example in Fig. 3(a). Note that $\langle Y \rangle_{neq}$ depends on α , and thus on the energy transfer, while $\langle Y \rangle_{eq}$ obviously does not.

Other relevant statistical quantities are sensitive to the small scale details of the distribution, and have a more complex behavior. This is the case of the entropy

$$S = - \sum_{\{n_{j,i}\}} P_{st}(\{n_{j,i}\}) \ln P_{st}(\{n_{j,i}\}). \quad (16)$$

As for $\alpha < -1$, T_j drops from T_{ext} to zero for $k_j \approx K$, it is natural to expect that the entropy S is proportional at large K to the number N_K of sites (j, i) with $k_j \leq K$, namely $N_K = mK/(m-1)$. This behavior is confirmed in Fig. 3(b) where the normalized entropy S/N_K is plotted as a function of α for different small values of D : S/N_K converges to a well-defined value for $\alpha < -1$, while no clear convergence is observed for $\alpha > -1$. Such a result can be understood in the framework of the simplified model where $\Delta_M = \nu_0 K^\alpha$ and $\Delta_j = 0$ for $j < M$. For large K , S is proportional to N_K if $\alpha < -1$ and

to $N_K^{|\alpha|}$ if $-1 < \alpha < 0$, while S is independent of N_K for $\alpha > 0$. Hence the dissipative state characterized by $P_{neq}(\{n_{j,i}\})$ has a much lower entropy than the quasi-equilibrium state obtained for $\alpha < -1$. In other words, the accessible volume in phase space is much smaller in far-from-equilibrium states than in equilibrium states.

A major challenge for future work would be to characterize such asymptotic nonequilibrium states in more realistic models, and to understand their statistical foundations. The fluctuation properties, and specifically the validity of Gallavotti-Cohen relations [19, 22] in these states, would be issues of great interest [26].
